Observation of interference in the quantum Hall regime may be hampered by a small edge state velocity due to finite phase coherence time. Therefore designing two quantum point contact (QPCs) interferometers having a high edge state velocity is desirable. Here we present a new simulation method for designing heterostructures with high edge state velocity by realistically modeling edge states near QPCs in the integer quantum Hall effect (IQHE) regime. Using this simulation method, we also predict the filling factor at the center of QPCs and their conductance at different gate voltages. The 3D Schrödinger equation is split into 1D and 2D parts. Quasi-1D Schrödinger and Poisson equations are solved self-consistently in the IQHE regime to obtain the potential profile, and quantum transport is used to solve for the edge state wave functions. The velocity of edge states is found to be $\langle E \rangle / B$, where $\langle E \rangle$ is the expectation value of the electric field for the edge state. Anisotropically etched trench gated heterostructures with double-sided delta doping have the highest edge state velocity among the structures considered.

1. INTRODUCTION

Electronic interferometers have been used as tools to probe the behavior of edge states in the quantum Hall regime. A typical electronic interferometer consists of two quantum point contacts (QPCs), which act as electron beam splitters, in analogy to optical interference experiments. Electrons traversing the interferometer’s path accumulate an Aharonov-Bohm phase equal to $2\pi$ times the number of magnetic flux quanta encircled. This phase can be controlled either by varying the area of the device or changing the magnetic field, yielding conductance oscillations. A major challenge for electronic interferometry is that the interfering particles must maintain phase coherence throughout their trajectory around the interference path. This is possible only if the quasiparticle edge state velocity is high enough that the time taken to traverse the interference path is smaller than the phase coherence time. Unsurprisingly, a strong correlation has been observed between the edge state velocity and the visibility of interference because the neutral modes are expected to propagate with a much lower velocity than the charge modes [15,16]. Thus, optimizing device parameters to maximize the velocity of edge modes is critical to observing interference in the FQHE regime.

The drift velocity of charge carriers in the classical Hall effect is equal to the ratio of electric field to magnetic field, $E / B$. On general grounds, the edge state velocity in the quantum Hall regime is expected to be proportional to the velocity scale set by $E / B$, where in this case the electric field $E$ is due to the confining potential at the edge. Experiments in the IQHE have confirmed that the edge velocity is approximately proportional to $1 / B$ [7,17–19]; however, a framework for analyzing the confinement potential and predicting the velocities in different heterostructures and gating schemes is needed. While for concreteness we analyze edge velocities in the IQHE regime, the principle that edge state velocity increases for a sharper confining potential is expected to generalize to the fractional regime as well [15,16]. Additionally, it has been found that precise tuning of the quantum point contacts is required to achieve interference [7], so we seek to understand the behavior

hsahasra@purdue.edu
of QPCs both in the quantum Hall regime and at zero magnetic field. We focus on the case of GaAs/AlGaAs heterostructures with 2DEG edges defined by metallic gates.

Numerical simulations have proven to be valuable tools for designing heterostructures [20] and gated devices [21,22], as well as in explaining the results of experiments in the quantum Hall regime [23,24]. The Poisson equation has been previously solved computationally in the IQHE regime for GaAs/AlGaAs heterostructures using a Thomas-Fermi approximation (TFA) to calculate the electron density and potential due to QPCs [21,22,25]. However, in these works, the doping ionization is not considered self-consistently. Also, these works model doping and quantum well regions in two dimensions instead of three dimensions. Taking these parameters into account is essential for correctly modeling the electric field at the edges, and in turn, the edge state velocity.

In this paper, we present a method for calculating electron edge state velocities and electron density in gated QPCs in the IQHE regime. We use a tool which we have developed in the NEMO5 [26] package for self-consistently solving the three-dimensional Schrödinger and Poisson equations in the IQHE regime. Following Stopa et al. [27] and Fiori et al. [28], the 3D Schrödinger equation is split into 1D and 2D parts. The electron interactions are calculated using the mean-field Hartree approximation in electrostatic simulations. We employ a frequently used incomplete ionization model for dopants in which Fermi-Dirac statistics and a donor energy level is used. We also solve the full 3D Poisson equation by accounting for the thickness of doping layers and 2DEG. Electrostatic simulations solve the potential landscape and use a Gaussian broadened Landau level density of states in the IQHE regime. The potential obtained is used in quantum transport simulations [29] to solve the 2D Schrödinger equation with open boundaries for the QPCs and calculate the edge state wave functions.

We compare the calculated conductance for QPCs with experimentally measured values to benchmark our simulations. Figure 1 details the heterostructure and QPC gate layout used for benchmarking. On the experimental side, the heterostructure was grown by molecular beam epitaxy (MBE) and Ti/Au metal gates were deposited on the surface. The devices used in the experiment have the same physical dimensions as in the simulation. We also compare the experimental 2DEG density with simulations to tune certain parameters such as donor ionization energy. The methodology used in this paper is discussed in Sec. II. The method is benchmarked with experiments in Sec. IIIA. Sheet density, subband energy, and edge state wave-function profiles are discussed in the rest of Sec. III. In Sec. IV, we study the edge state velocity as a function of magnetic field and gate voltage for four different structures in an attempt to maximize the velocity.

II. METHODOLOGY

Typically, interference experiments operate with small source-drain biases on the order of μV to avoid heating the 2DEG [7,30]. The subband energy of electrons due to the confinement in the quantum well varies on the order of meV and is much larger than the applied bias. The source-drain bias is thus neglected in electrostatic simulations. The overall repulsive effect of electron density on itself is calculated by solving the Schrödinger equation self-consistently with the Poisson equation, which is a standard practice for modeling quantum systems [31]. The two equations are discretized using a nonuniform mixed element finite element mesh [Fig. I(c)]. Self-consistent iterations are done using a quasi-Newton method based on the predictor-corrector method [32]. Further details on discretization and numerics can be found in Ref. [33]. Figure 2 shows the simulation flow.
of a substitutional Si atom along the [111] direction [40]. There exists a potential barrier for the trapping and detrapping of electrons in DX centers which results in freezing out the electrons at low temperatures. Hence the only participating donors are those which remain ionized as the device is cooled down to millikelvin temperatures.

The Fermi level pinning on the exposed top GaAs/AlGaAs surfaces is included in the model for QPCs using Neumann boundary conditions in the Poisson equation (1). Charge density on the exposed surface due to occupied dangling bonds creates a Schottky barrier [41]. The Schottky barrier can be modeled by setting a constant voltage (usually $-0.7$ to $-0.8$ V) with respect to the Fermi level at the top surface using the Dirichlet boundary condition [42]. To model the Fermi level pinning, an electric field can also be specified at the top using the Neumann boundary condition [43]. The electric field is calculated from the slope of the conduction band when Dirichlet boundary condition is used in 1D simulations. Setting the electric field at the top is equivalent to having frozen charges at the top surface. Other more complicated models [24,44,45] can be used to specify a density of states at the surface, which lead to Fermi level pinning. The potential and the density in the QPC channel are affected by the boundary condition of the exposed surface as shown for heterostructures with shallow 2DEG [28].

### B. Schrödinger equation

The free electrons in the quantum well at the GaAs/AlGaAs interface occupy the lowest subband in the GaAs conduction band gamma valley and can be approximated by a parabolic dispersion relation [31]. The Schrödinger equation can thus be simplified using an effective-mass description:

$$-\frac{\hbar^2}{2m^*} \nabla \cdot \left( \frac{1}{m^*(r)} \nabla \psi(r) \right) + V_{\text{ext}}(r) \psi(r) = E \psi(r), \quad \text{(3)}$$

where $m^*(r)$ is the position dependent effective mass, which here is taken to be a constant 0.067$m_e$ for both GaAs and AlGaAs gamma valleys. $V_{\text{ext}}(r) = E_C(r) - q\phi(r)$, where $\phi$ is the electrostatic potential in the Poisson equation (1). The electrostatic potential changes slower in the lateral direction than in the growth direction. Following the work of Fiori et al. [28], the 3D wave function can thus be expanded as $\psi(x,y,z) = \chi(x,y) \chi(x,y)$. Here, $\chi$ is the 1D wave function along $fZ$ (growth) axis evaluated at different points in the $X-Y$ plane. $\chi$ is the 2D envelope along the lateral direction. The 3D Schrödinger equation can be separated into 1D and 2D parts by substituting the expression for $\psi$:

$$-\frac{\hbar^2}{2m^*} \frac{\partial^2 \chi}{\partial z^2} + V_{\text{ext}} \psi = \hat{E} \chi, \quad \text{(4)}$$

$$-\frac{\hbar^2}{2m^*} \nabla^2 \chi + \hat{E}_i = E \chi, \quad \text{(5)}$$

$\hat{E}_i \equiv \hat{E}_i(x,y)$, called the subband energy, is the eigenvalue corresponding to $\psi_i$. We assume the subband energy to be flat as it is slowly varying and calculate the approximate electron density.
density to be used in self-consistent simulations:

\[
n(x, y, z) = \frac{kT m^*}{\pi \hbar^2} \sum_{i=1}^{\infty} |\psi_i(x, y, z)|^2 \times \ln \left[ 1 + \exp \left( -\frac{E_i(x, y) - E_F}{kT} \right) \right]. \tag{6}
\]

The logarithmic term comes from integrating the density of states of a parabolic dispersion for 2D periodic systems.

For QPCs, Eq. (5) has open boundary conditions and needs to be solved using quantum transport algorithms (discussed in Sec. II C) to model the transmission, resistance, quantum current density, and edge state velocity. Electrostatic simulations require the electron density for self-consistently obtaining the electrostatic potential. Using quantum transport algorithms to calculate the density in micrometer-sized structures is computationally prohibitive. Ballistic transport simulations produce a delta function DOS in the bulk for the Landau levels, for which the energy is difficult to pinpoint, requiring a fine energy grid for integrating the electron density. Adding inelastic scattering terms to the quantum transport equations for broadening the Landau level DOS would further increase the computational requirements. Making the assumption of a slowly varying subband energy in Eq. (5) to analytically integrate the electron density for the electrostatic simulations is computationally efficient, but neglects the lateral spread of the edge state wave function. The subband energy profile obtained from electrostatic simulations is used to solve Eq. (5) with open boundaries. This approach has been shown to match the experimental QPC conductance in zero magnetic field [28].

1. Integer quantum Hall regime

The method described in the previous section is employed in the IQHE regime, where Gaussian broadened Landau level density of states is used. In the presence of a perpendicular magnetic field, Eq. (5) can be rewritten as

\[
\frac{(i \hbar \nabla + eA)^2}{2m^*} \chi + \hat{E}_i + g \mu_B B \sigma_z = E \chi, \tag{7}
\]

where \(A\) is the vector potential, \(g\) is the Landé \(g\) factor (discussed later), \(\mu_B\) is the Bohr magneton, and \(B\) is the magnetic field. The assumption of a slowly varying \(\hat{E}_i\) is employed again, which reduces equation (7) to that of noninteracting electrons trapped in 2D in presence of a perpendicular magnetic field. Then, solving (7) gives us the Landau level (LL) density of states (DOS) for the \(i\)th subband:

\[
D^j_B = \frac{1}{2\pi l_B^2} \sum_{n=0}^{\infty} \left[ \delta(E - E^+_i) + \delta(E - E^-_i) \right],
\]

\[
E^+_i = \hat{E}_i + (n + 1/2) \hbar \omega_c + g \mu_B B,
\]

\[
E^-_i = \hat{E}_i + (n + 1/2) \hbar \omega_c - g \mu_B B,
\]

where \(l_B = \sqrt{\hbar/eB}\) is the magnetic length and \(\omega_c = eB/m^*\) is the cyclotron frequency. The \(\hat{E}\) term introduces a position dependence to the LL energy. This expression was used by Chklovskii et al. [47] for calculating electrostatics at the edges in the IQHE.

Real devices have broadened LL DOS due to disorder, collision broadening, and effects due to a finite wave-function width, which has been studied in detail by others [48]. To account for these effects, a Gaussian spread DOS around the LL is used:

\[
\bar{D}^i_B = \frac{1}{2\pi l_B^2} \sum_{n=0}^{\infty} \frac{1}{\sqrt{2\pi \Delta E}} \left[ \exp \left( -\frac{(E - E^+_i)^2}{2\Delta E^2} \right) \right. \]

\[
+ \left. \exp \left( -\frac{(E - E^-_i)^2}{2\Delta E^2} \right) \right]. \tag{9}
\]

\(\Delta E = \gamma \hbar \omega_c\) is a parameter that defines the spread of the states around the LL energy. The electron density can thus be written as

\[
n_B(x, y, z) = \sum_{i=1}^{\infty} \int_{-\infty}^{\infty} \frac{1}{1 + \exp \left( \frac{E - E^+_i}{kT} \right)} \left| \psi_i(x, y, z) \right|^2 \bar{D}^i_B \ dE. \tag{10}
\]

Güven and Gerhardts investigated the effect of changing \(\gamma\) and temperature on the potential profile [48,49]. They calculated the potential profile for different values of \(\gamma\) and \(t = kT/\hbar \omega_c\). In this paper, we use the value \(\gamma = 0.05\), which amounts to a standard deviation of 5% of the LL spacing. \(t\) is a dimensionless parameter that represents the relative strengths of thermal and magnetic energy scales. They showed that the incompressible region width decreases by roughly 50% when the temperature is increased from \(t = 1\) to \(2\) for \(\gamma = 0.025\). Typical electron temperatures for interferometry experiments range from 10–300 mK and magnetic fields are in the range 0.5–10 T [50]. For these parameters, \(t\) is in the range 5 × 10^{-5} to 3 × 10^{-2}. We can thus approximate the Fermi function as a step function without affecting the width of incompressible regions more than the mesh spacing. Evaluating Eq. (10) with a step Fermi function gives us

\[
n_B(x, y, z) = \frac{1}{4\pi l_B^2} \sum_{i=1}^{\infty} \left( \int_{E_F}^{E^+_i} + \int_{E^-_i}^{E_F} \right) \left| \psi_i(x, y, z) \right|^2 \bar{D}^i_B \ dE.
\]

The first term in the summation comes from integrating the half Gaussian curve under the LL energy. The second term comes from integrating the density of states lying between the LL energy and the Fermi level. \(+\) or \(-\) sign is used when the Fermi level is above or below \(E^+_i\) and \(E^-_i\), respectively. Using the expression in Eq. (11) for density helps with convergence and gradually increasing magnetic field and temperature from 0 is not required.

2. Landé \(g\) factor

The \(g\) factor in bulk GaAs is 0.44; however, for two-dimensional electrons in the quantum Hall regime, the spin splitting is enhanced due to exchange interactions, and experimental measurements of the spin gap in GaAs/AlGaAs heterostructures have yielded effective \(g\) factors up to 11.65 [51].
The interactions between spin-polarized electrons which lead to this enhanced spin splitting can be taken into account using the local spin density approximation (LSDA) [52]. To compare the potential landscape with and without spin splitting, we performed calculations using an effective $g$ factor of 5.2, the same as the value used by Bilgeç et al. [52], so that our results may be compared with the results using LSDA. We found that there is no substantial effect on the incompressible strip widths due to the low magnetic field range and Landau level broadening.

### C. Quantum transport

2D wave functions of the edge states can be obtained by solving Eqs. (5) or (7) with open boundary conditions using the nonequilibrium quantum transport methods based on nonequilibrium Green’s functions (NEGF) [53,54] or the quantum transmitting boundary method (QTBM) [55]. This work uses the software KWANT [29], which is based on a wave-function approach similar to QTBM for solving the open system. The effective 2D Hamiltonian [33] is discretized using a finite difference method with a square grid of spacing $a = 3$ nm. The effective mass Hamiltonian with 3-nm grid has a parabolic dispersion within the relevant energy range of 6 meV above the conduction band minimum in the absence of magnetic field. In the IQHE regime, the vector potential is included in the Hamiltonian using Peierls phase approximation. A Landau gauge is used for calculating the vector potential since translational symmetry is required in the Hamiltonian.

Incoming and outgoing transverse modes in the QPC scattering region are calculated by solving eigenvalue problems in the cross-section away from the QPC. The 2D Schrödinger equation in the QPC scattering region is then solved as a linear equation in the cross-section away from the QPC. The 2D Schrödinger equation in the QPC scattering region is then solved as a linear equation in the cross-section away from the QPC.

The local current density of a particular mode between two grid points $(i,j)$ and $(i',j')$ is calculated using the current operator

$$I_n((i,j) \rightarrow (i',j')) = 2 \text{Im}(\chi^{i,j}_n \chi^{i',j'}_n).$$

where $\mathcal{H}_{i,j,i',j'}$ is the matrix element between grid points $(i,j)$ and $(i',j')$. The transmission of each mode at the Fermi level, $T_n(E_F)$, is obtained directly from KWANT. We assume that the resistance is in the linear regime, since the Fermi window is narrow at low temperature and the source drain bias is on the order of $\mu$V. This assumption essentially means that the edge states are in equilibrium with the bulk, since the linear regime resistance is an equilibrium property. The linear response resistance of the QPC at low temperature can be written as [53]

$$R = \frac{\hbar}{e^2} \left( \sum_v T_v(E_F) \right)^{-1}. \quad (14)$$

### III. RESULTS

#### A. QPC resistance benchmark with experiment

Figure 3 shows a comparison between measured and computed resistance for a 300-nm-wide QPC for the 91-nm-deep 2DEG heterostructure. The resistance measurement was done at 300 mK, with no magnetic field using a constant ac current source of 10 nA. The computed resistance shows a good match with the experimentally measured values. The discrepancies between calculated and measured resistance are near depletion (low negative voltage) and pinch-off (high negative voltage) regimes, and agreements are in between these regimes. The electron beam lithography system used to define the QPC has an effective resolution of approximately 20 nm, so variations in the true width of the QPC on the order of 20 nm are expected, which could lead to additional discrepancy.

The computed depletion voltage is about twice the measured value, because a simple one-level donor ionization model is used and the physics of DX center formation is not captured. Also, below the depletion gate voltage, the experimental resistance falls to zero, whereas in the simulations the boundary of the 2DEG is the simulation domain (which is much smaller than a Hall bar) leading to a minimum finite resistance. Due to this unphysical condition, the simulated resistance is not shown for gate voltages above the depletion point. Near the pinch-off, the source-drain bias is the highest and thus the accuracy of Eq. (14) is smaller than at lower voltages. The Thomas-Fermi approximation used to compute the density of states laterally gives an inaccurate electrostatic potential in the QPC near pinch-off. Despite these minor discrepancies, the overall agreement between the experiment and simulation is satisfactory between the depletion and pinch-off regimes.
gate voltages at a magnetic field of 2 T. (c) and (d) show cuts along the and because of the dominating electrostatic forces due to the dipolar strips form as a result of LLs crossing the Fermi level, density in the presence of a magnetic field of 2 T. For a sheet density of $1.34 \times 10^{11}$ cm$^{-2}$, a single incompressible strip is expected in the presence of a magnetic field of 2.2 T. The incompressible strip can be seen as a band of light green with a density around $1 \times 10^{11}$ cm$^{-2}$ near the edges. Using electrostatic simulations, the electron density in the middle of the QPC can be obtained for different gate voltages and magnetic fields. This helps in designing QPCs with the required channel width so that the velocity can be maximized keeping a certain filling fraction in the middle. The correctness of density and potential profiles can be verified by comparing the conductance of the constriction for different gate voltages with experiments. The conductance can be calculated using quantum transport simulations.

Figure 5 also shows traces of the first subband energy and 2DEG sheet density obtained from quantum transport simulations. The conductance is calculated by summing up the transmission due to all the modes at the Fermi level. Figure 6 plots conductance of the QPC at three different magnetic fields. The electron density and filling factors are obtained from independent electrostatic simulations. The quantum transport simulations independently show that the extended states lie at the center of LL density of states, which means that the conducting edge states lie in the compressible regions.

C. QPC conductance in the IQHE regime

The conductance is calculated by summing up the transmissions due to all the modes at the Fermi level. Figure 6 plots conductance of the QPC at three different magnetic fields. The conductance shows exactly quantized plateaus in units of $e^2/h$ when the modes are either completely transmitted or reflected by the QPC. We get $v = 1$ conducting modes when the bulk filling factor is close to an even integer. This is because the modes in the $v$ Landau level at that filling fraction have a very small velocity as we will show later in Sec. IV A. The electron density and filling factors are obtained from electrostatic simulations. The quantum transport simulations independently show that the extended states lie at the center of LL density of states, which means that the conducting edge states lie in the compressible regions.
FIG. 6. Conductance vs applied gate voltage of a 300-nm wide QPC at magnetic fields of 0.9, 1.36, and 2.71 T, and bulk filling factors of $\nu_{\text{bulk}} = 6.00, 3.97,$ and 1.99, respectively. Each point represents an independent electrostatic simulation. The edge mode of even $\nu$th Landau level starts conducting just above a bulk filling factor of $\nu_{\text{bulk}} = \nu$. This is why we have conductance corresponding to one less edge state than the filling factor.

D. Edge state wave functions in the QPC scattering region

Figure 7 shows edge mode wave functions at $V_G = -0.34$ V and 0.9 T (bulk filling factor of $\nu_{\text{bulk}} = 6$) for a QPC. Figures 7(a) and 7(b) have fully transmitted and Fig. 7(c) has fully reflected edge states, respectively. In this simulation, the spin is neglected and we only calculate the wave functions for the spinless Landau levels $n$. The wave functions for $n = 1, 2,$ and 3 have 1, 2, and 3 lobes, respectively, similar to the harmonic oscillator wave functions of the bulk 2D IQHE Hamiltonian in the Landau gauge. The wave functions for different spins in the same Landau level $n$ have the same functional form. The current densities calculated using Eq. (13) are shown using black arrows. Interestingly, the local current density changes direction for $n = 2, 3$ [Figs. 7(b) and 7(c)] and goes opposite to the direction of flow of current. Qualitatively, this may be understood semiclassically as the motion of the guiding center of the cyclotron orbit. Pile up of charge can be seen at the corners of the QPC defined 2DEG where the wave functions bend.

IV. OPTIMIZATION OF EDGE STATE VELOCITY

In this section, we calculate velocities of edge states of different Landau levels as a function of gate voltage and magnetic field for different structures. We use Eq. (12) for calculating the velocity of the edge states. We found that the velocity obtained from this equation is equal to $\langle E \rangle / B$, where $\langle E \rangle$ is the expectation value of the electric field for the edge state wave functions. The goal of this section is to design heterostructures and gates to obtain a strong electric field at the 2DEG edges that yield high edge state velocities. The velocity saturates even though electric field near the gate gets stronger, due to the finite width of the edge state wave function. Therefore the correct metric for defining the strength of the electric field is the velocity of the edge states, or the expectation value of the electric field for the edge state wave functions $\chi$. In this section, the velocities of propagating modes are evaluated in the semi-infinite region, thus they are the injection velocities of propagating modes. Velocities calculated elsewhere in the device, but away from the middle region of the QPC, are found to be close to the injection velocities.

We consider four different structures as shown in Fig. 8 in an attempt to maximize the velocity of edge states. The first structure [Fig. 8(a)] is the same as Fig. 1 with top gates. In the second structure [Fig. 8(b)], the doping is moved closer to the 2DEG from 17–31 nm depth to 40–54 nm depth to increase the 2DEG bulk DOS. A depletion top gate is added on the bulk interferometer region to get the same bulk density as the first structure. The gate which defines the edge of the 2DEG is separated from the bulk depletion gate by 100 nm. The idea behind this design is the improve the electric field by making a higher 2DEG DOS available near the edge. The third structure [Fig. 8(c)] has the same heterostructure as the first structure, but uses trench gates with vertical trench walls which can be made using anisotropic etching techniques. Anisotropic etch trench gates, which are etched past the doping region,
have a stronger effect on the 2DEG because the screening due to doping is removed. The fourth structure [Fig. 8(d)] has double-sided delta doping with trench gates etched past the top doping layer, but not past the quantum well and the bottom doping layer. There remains a 25-nm AlGaAs spacer between the trench metallic gate and the quantum well. The 10-nm-wide quantum well is at a depth of 155 nm and separated from the doping layers by 45 nm on both sides. The bulk 2DEG density in this heterostructure is $2.11 \times 10^{11}$ cm$^{-2}$ as compared to $1.34 \times 10^{11}$ cm$^{-2}$ in the other three structures. Keeping the second doping layer helps pull the electrons closer to the gate and thus increases the edge electric field.

A. Magnetic field dependence of velocity

The expectation values of the electric field for edge states of the $n$-Landau levels are plotted as a function of the spin-less bulk filling factor for the four different structures in Fig. 8. We plot the electric field expectation for the spin-less edge state wave functions in Fig. 8 to compare the compressible strips widths. The top gated structures require a negative bias on the top gate to deplete the 2DEG, whereas the 2DEG under trench gates is depleted at 0 V because of the etched doping. A positive bias is applied in the fourth structure to pull the electrons towards the gate. It can be seen from the plots that the electric field expectation value goes to zero as the magnetic field is increased, for the edge states of Landau levels that are partially filled. The electric field expectation value for partially filled Landau levels starts dropping to zero close to half-filled bulk Landau level, which means that the edge (extended) states lie at the center of the Landau level DOS.

The two features that define the sharpness of the edge are the maximum value of $\langle E \rangle$ and its slope as a function of the filling factor. Both these features depend on the width of compressible region. The compressible region is narrower in a structure as compared to another at a particular magnetic field (equal subband energy drop across the compressible regions in the two structures), when $\langle E \rangle$ is stronger in that structure. Due to this, the slope of $\langle E \rangle$ as a function of the bulk filling factor is also steeper because the width of the compressible region decreases to a smaller value. The electric field in the trench gated double delta doped structure is the highest among the four structures (Fig. 8).

Figures 9 and 10 plot the edge state velocities for structures 8(a) and 8(d), respectively, when the spin is included in the Hamiltonian. With spin included, the edge state wave functions, which were in the center of the compressible region when spin was excluded, split into two and move towards
FIG. 11. Velocities of edge modes for the outermost \((n = 1)\) \(n\)-Landau level in the same four structures as in Fig. 8 at different magnetic fields are plotted as a function of the gate voltage. The spinless bulk filling factors for the plotted magnetic fields are (a) \(n_{\text{bulk}} = 3.04, 1.51, \) and 1.14; (b) \(n_{\text{bulk}} = 2.96, 2.12, \) and 1.27; (c) \(n_{\text{bulk}} = 3.75, 1.88, \) and 1.40; and (d) \(n_{\text{bulk}} = 2.93, 2.14, \) and 1.44, respectively.

opposite ends of the compressible region. This can be seen in Fig. 5 for \(\nu = 1.2\). This is due to the Zeeman energy and the large effective spin splitting due to interactions [51]. Edge states with opposite spin from consecutive \(n\)-Landau levels lie close to each other, e.g., in Fig. 5 for \(\nu = 2.3\). Therefore the velocity of even \(\nu\)-Landau level edge states goes to zero just below the corresponding \(\nu\) bulk filling factor as the wave function is close to the inner edge of the compressible region. The velocity of odd \(\nu\)-Landau level edge states goes to zero close to \(\nu - 1\) bulk filling factor as the wave function is close to the outer edge of the compressible region. This explains the maximum conductance in Fig. 6 (conductance plot for the QPC in the IQHE regime). From these plots, we can infer that the edge state velocity has an upper limit due to a finite width of the edge state wave functions. The velocities are also affected by the electrostatics. This can be clearly seen for the inner edge states, whose velocity decreases close to the even integer \(\nu_{\text{bulk}}\) bulk filling factor and forms plateaus in between.

Our results explain the visibility going to zero close to \(\nu_{\text{bulk}} = 1\) and 2 for well defined outer and inner edge channels, respectively, in the interferometer visibility measurements of Gurman et al. [1]. For higher bulk filling fractions, low velocity (due to the slow moving neutral modes possibly caused by Coulomb interactions) and interedge scattering causes a drop in visibility [1], which cannot be predicted using our model. The velocities predicted by our model fall reasonably close to the experimentally measured values; for example, \(~0.5–1.5 \times 10^5\) m/s measured by Mcclure et al. [7] and \(~2–8 \times 10^4\) m/s measured by Gurman et al. [1]. We predict that the velocities in the trench gated structures are higher only by a factor between 1–2 and as much as 10 at certain filling factors for the outer edge.

B. Gate voltage dependence of velocity

The edges of the 2DEG in the interferometer region are defined by either negatively biased top gates or by trench gates. The 2DEG in the top gated structures is not depleted until a certain negative gate voltage is reached as the doping layer screens the top gate. Trench gated structures, on the other hand, have depleted 2DEG irrespective of the applied gate voltage when the doping layer is also etched. A positive gate bias can then be applied on the trench gates to pull the edge of the 2DEG closer to the lithographically defined edge to possibly get a larger edge electric field. In this section, we compare the edge state velocities for top and trench gated structures and study their dependence on the gate voltage.

Figure 11 plots the velocity of the outermost \(n\)-Landau level edge mode at different magnetic fields as a function of the gate voltage for the four structures studied in the previous sub-section. The velocity for the top gated structure [Fig. 11(a)] increases as more negative voltage is applied on the gate and saturates at a certain value. This shows that the 2DEG is screened by the doping layer and the edge potential is the steepest when the doping layer is depleted. Figure 11(b) shows velocities at high negative gate voltages in the saturated regime. We can see a peak in the velocity near \(-0.6\) V for \(B = 1.5\) T. This is because the edge state moves from under the outer top gate to under the inner top gate while passing through the region with exposed surface. This shows that the region with exposed surface has a larger electric field due to a higher availability of local density of states. This effect is not seen at \(B = 0.7\) and 0.9 T because the wave functions become wider as the magnetic field is reduced and the electric field is averaged out over a larger area. Figures 11(c) and 11(d) are for the trench gated structures. The velocity increases in Fig. 11(c) as the gate voltage becomes more positive for \(B = 2.4\) T. We propose that this occurs because the edge state wave function is pulled closer to the sharper edge potential near the lithographic edge. This effect is less pronounced at lower magnetic fields where the wave functions are wider. Figure 11(d) shows negligible dependence of the edge state velocity on the gate voltage for the double-sided doped trench-gated structure. Our understanding is that this is due to the positively charged lower doping layer pulling the edge state wave function closer to the lithographic edge. The gate voltage only changes the location of the edge state and not the electric field expectation value.

C. Quantum well width dependence of velocity in double-sided delta doped structure

In this section, we study the effect of changing the quantum well width for the double-sided delta doped structure in Fig. 8(d). Figure 12 plots the average of the edge state velocity for the \(n = 1\) Landau level, calculated over the range of gate voltages in Fig. 11(d). In general, \((\langle E \rangle)\) for edge states increases with the bulk 2DEG sheet density. The bulk 2DEG sheet density increases as the quantum well width is increased;
therefore, the velocity also increases with the quantum well width for this structure. However, the quantum well width cannot be arbitrarily increased as this will lead to the formation of a bilayer sheet density. Also, higher magnetic fields are required to get the same filling fraction for larger quantum well widths. The 9-, 10-, and 11-nm-wide quantum wells have 2DEG sheet densities of $1.93 \times 10^{11}$, $2.11 \times 10^{11}$, and $2.20 \times 10^{11}$ cm$^{-2}$ respectively.

V. SUMMARY

We have presented a simulation method for comparing the edge state velocity in different structures and designing the heterostructures for increasing the velocity. We have implemented a way of solving Schrödinger and Poisson equations self-consistently in QPCs defined on GaAs/AlGaAs heterostructures, for obtaining the electron density and electrostatic potential in the IQHE. A set of one-dimensional wave functions self-consistently in the IQHE Hamiltonian in the Landau gauge and for a spatially varying electric field. The velocity of edge states calculated using quantum transport simulations matches with $\langle E \rangle / B$, where $\langle E \rangle$ is the electric field expectation value for the edge states. The edge state velocity has an upper limit due to a finite width of the edge state wave functions. We also compare the magnetic field and gate voltage dependence of the edge state velocity for different structures. We conclude that the velocity in the double delta doped anistropic etched trench gated structures is the highest among the four structures considered. We also showed that the velocity increases with the quantum well width in double side doped structures.

Our results can be used to understand some of the visibility and velocity measurements of electronic interferometers operating in the integer quantum Hall regime [1,7]. The device designs we have proposed may lead to improved edge state velocity and thus improved performance of future interferometers, and may enable the observation of interference in the fractional quantum Hall regime.
