(Received 9 May 2013; accepted 13 June 2013; published online 25 June 2013)

We report on the growth and electrical characterization of modulation-doped $\text{Al}_{0.24}\text{Ga}_{0.76}\text{As}/\text{Al}_{x}\text{Ga}_{1-x}\text{As}/\text{Al}_{0.24}\text{Ga}_{0.76}\text{As}$ quantum wells with mole fractions as low as $x = 0.00057$. Such structures will permit detailed studies of the impact of alloy disorder in the fractional quantum Hall regime. At zero magnetic field, we extract an alloy scattering rate of 24 ns$^{-1}$ per% Al. Additionally, we find that for $x$ as low as 0.00057 in the quantum well, alloy scattering becomes the dominant mobility-limiting scattering mechanism in ultra-high purity two-dimensional electron gases typically used to study the fragile $\nu = 5/2$ and $\nu = 12/5$ fractional quantum Hall states.

© 2013 AIP Publishing LLC. [http://dx.doi.org/10.1063/1.4812357]

Presently the fractional quantum Hall effect (FQHE) in the 2nd Landau level (LL) is under intense scrutiny.1–14 It is speculated that the exotic fractional states at filling factors $\nu = 5/2$ and $\nu = 12/5$ may support low-lying charged excitations that obey non-Abelian braiding statistics.15–19 For particles obeying non-Abelian statistics repeated interchange of two identical particles does not change the many-body wavefunction by a factor of $+/−1$ as for bosons and fermions, respectively, but, rather, results in a unitary transformation of the wavefunction within a degenerate manifold. If the $\nu = 5/2$ and $\nu = 12/5$ states do indeed support non-Abelian excitations, they may provide a viable platform for quantum computations that is topologically protected from decoherence. However, excitation gap energies for FQHE states in the 2nd LL are typically quite small, presumably limited by disorder. The largest gap measured at $\nu = 5/2$ amounts to $\Delta = 570$ mK and the gap at $12/5$ is below $100$ mK, while the theoretical estimate for the $5/2$ gap in the density range of current experiments is $\Delta = 1.8$ K.21–23 It is, therefore, of considerable interest to understand how different types of disorder (e.g., long-range Coulomb scattering, short-range alloy disorder, and interface roughness scattering) impact the measured excitation gaps.7,24–26

Alloy disorder scattering occurs when electrons traverse a region of a semiconductor comprised of a random solution of two or more binary semiconductors. $\text{Al}_{x}\text{Ga}_{1-x}\text{As}$ is such a random alloy in which $x$ is the mole fraction of aluminum in solution. In the case of $\text{Al}_{x}\text{Ga}_{1-x}\text{As}$ alloy disorder scattering is essentially short-ranged, arising from the replacement of a Ga atom with an isovalent Al atom and is described in Ref. 27. It is operative on the scale of the unit cell and can be represented as a sum of delta-function scattering potentials. Li et al.28 studied alloy scattering of two-dimensional electrons in $\text{Al}_{0.33}\text{Ga}_{0.67}\text{As}/\text{Al}_{x}\text{Ga}_{1-x}\text{As}$ single heterojunction. They determined an alloy scattering rate of $35$ ns$^{-1}$ per% Al and an alloy scattering potential $U = 1.13$ eV. Importantly, Li and collaborators used these samples to establish scaling and universality of the integer quantum Hall plateau-to-plateau transitions.29 However, the heterostructure design described in Ref. 28 does not produce samples of sufficient quality to study the fragile FQHE of the 2nd LL. Additionally, samples with even lower alloy content in a quantum well and over a broader range of $x$ are necessary for studies of the 2nd LL.

In this letter we describe the growth and electrical characterization of modulation-doped $\text{Al}_{0.24}\text{Ga}_{0.76}\text{As}/\text{Al}_{x}\text{Ga}_{1-x}\text{As}/\text{Al}_{0.24}\text{Ga}_{0.76}\text{As}$ quantum wells with alloy levels down to $x = 0.00057$ incorporated into a modern heterostructure design that is typically employed in studies of the FQHE in the 2nd LL. Samples were grown by molecular beam epitaxy (MBE) in a customized system specifically designed to grow ultra-high purity structures necessary to study the FQHE in the 2nd Landau level. This system has now produced many samples with electron mobility exceeding $20 \times 10^6$ cm$^2$/Vs and activation gaps for the $\nu = 5/2$ state $\Delta > 500$ mK. The MBE is configured with 2 aluminum and 2 gallium effusion cells so that heterostructures containing multiple values of alloy mole fraction $x$ can be grown without changing the effusion cell temperatures during growth. Reflection high energy electron diffraction (RHEED) intensity oscillations collected with a computer controlled CCD camera were analyzed to calibrate growth rates and the aluminum content in the barriers and quantum wells. A series of 10 samples with varying $x$ in the quantum well (including $x = 0$) were grown.

Our alloy-disorder samples are modulation doped $\text{Al}_{0.24}\text{Ga}_{0.76}\text{As}/\text{Al}_{x}\text{Ga}_{1-x}\text{As}/\text{Al}_{0.24}\text{Ga}_{0.76}\text{As}$ quantum well structures, consisting of a $30$ nm $\text{Al}_{x}\text{Ga}_{1-x}\text{As}$ quantum well sandwiched between $\text{Al}_{0.24}\text{Ga}_{0.76}\text{As}$ barriers. The structure is doped with Si at a setback of $75$ nm above and below the quantum well using a short-period superlattice doping scheme.30,31 We have found that this doping method consistently yields the largest energy gaps in the 2nd LL, and such large energy gaps are a necessary starting condition before intentionally adding disorder of any kind. In the 10 samples studied, the Al alloy content in the quantum well was then varied from $x = 0.0$ to $x = 0.0078$ (Fig. 1).
Heterostructures were grown on semi-insulating (100) GaAs substrates using a single Ga and two Al effusion cells. The primary Al cell was used to grow the Al$_{0.24}$Ga$_{0.76}$As layers while the secondary Al cell was used for introducing the small concentration of Al in the quantum well. The effusion cells were allowed to stabilize at their approximate growth temperatures for at least 30 min prior to fine tuning their respective growth rates via RHEED intensity oscillations. RHEED oscillations were observed along the [011] direction on the 2 × 4 reconstructed surface of GaAs with a CCD camera and custom data acquisition software. The long time scale associated with the AIAs oscillations of the secondary Al cell required special precautions. To minimize intensity fluctuations due to background lighting the RHEED screen and CCD camera were enclosed in a light tight box. The angle of the incidence for the RHEED beam was carefully tuned to provide the strongest oscillations. An azimuthal positioning process that controlled the approach direction minimized noise associated with azimuthal rotation gear tolerances of the sample mounting stage. We also found it necessary to reduce the RHEED electron gun filament intensity below its standard operating level to minimize drift of the specular spot due to charging of the substrate. This step allows for data collection from a very small area on the phosphor screen, eliminating background signal from the secondary Al cell required special precautions. To minimize intensity fluctuations due to background lighting the RHEED screen and CCD camera were enclosed in a light tight box. The angle of the incidence for the RHEED beam was carefully tuned to provide the strongest oscillations. An azimuthal positioning process that controlled the approach direction minimized noise associated with azimuthal rotation gear tolerances of the sample mounting stage. We also found it necessary to reduce the RHEED electron gun filament intensity below its standard operating level to minimize drift of the specular spot due to charging of the substrate. 

FIG. 1. A schematic band structure of the samples used in this study. Note that the Si dopants are placed in narrow GaAs quantum wells 75 nm above and below the principal 30 nm quantum well.

As the Al mole fraction was increased from $x=0.0$ to $x=0.0078$, the mobility decreased from $16 \times 10^6$ cm$^2$/Vs to $1.2 \times 10^6$ cm$^2$/Vs. Carrier mobility was measured using ~4 mm × 4 mm square samples contacted with In-Sn alloy annealed into the sample at 430 °C for 15 min in H$_2$/N$_2$ forming gas. The material was characterized at $T=300$ mK after illumination with a red light emitting diode using standard lock-in techniques with the density being determined from quantum Hall effect (QHE) minima. The carrier areal density of the samples used in this study shows no dependence on the Al mole fraction in the channel. The aluminum atoms added to the channel have the same number of valence electrons as the gallium atoms they replace and do not act as donors or acceptors.

The inverse scattering time due to alloy disorder $(1/\tau_{\text{alloy}})$ is expected to be proportional to $x(1-x)$.

In Figure 3 we plot the experimentally measured inverse total scattering time $(1/\tau_{\text{total}})$ vs. $x(1-x)$ along with a linear fit to the data. The total scattering rate $(1/\tau_{\text{total}})$ is given by Matthiessen’s rule as $1/\tau_{\text{total}} = 1/\tau_{\text{alloy}} + 1/\tau_{\text{other}}$, where $1/\tau_{\text{other}}$ represents scattering from all other temperature independent mechanisms. We neglect phonon scattering as it is
well known that phonon scattering does not contribute significantly to the mobility lifetime at $T = 0.3$ K.33–35 An alloy scattering rate of 24 ns$^{-1}$ per% Al was determined from the linear fit. We note that our extracted alloy scattering rate differs from the result quoted in Ref. 28 by more than 30%. We attribute this discrepancy to a neglect of a zero offset in Ref. 28. When we fit the data of Ref. 28 using the methods described here we find a scattering of 26 ns$^{-1}$ per% Al, more consistent with our measurements.

At this juncture two points merit discussion. The $x = 0$ intercept of the linear fit is significant. The linear fit suggests that the $x = 0$ intercept is approximately 3 ns$^{-1}$, while the actual measured value for the sample grown at $x = 0.0$ is 1.6 ns$^{-1}$. This offset, designated as $\delta$ in Fig. 3, is attributed to additional impurities introduced from the 2nd Al effusion cell and the surrounding material when the 2nd Al shutter is opened. This observation indicates that the diffusion cells themselves are still sources of impurities and points to a direction for future improvement in material quality. Note that this effect is only observable when starting with extremely high mobility samples. The second point concerns the small amount of alloy disorder necessary for alloy scattering to become the dominant scattering mechanism controlling the mobility lifetime. Our MBE system now routinely produces samples with mobility in excess of $2 \times 10^6$ cm$^2$/Vs. At $\mu = 20 \times 10^6$ cm$^2$/Vs the scattering rate $1/\tau = 1.3$ ns$^{-1}$. From the data of Fig. 3, it is clear that alloy disorder greater than or equal to $x = 0.0005$ will become the dominant mobility-limiting mechanism in state-of-the-art samples. While alloy disorder clearly impacts mobility, its influence on the FQHE limiting mechanism in state-of-the-art samples. While alloy disorder clearly impacts mobility, its influence on the FQHE...
